(2) Water-Soluble Vitamins

Vitamin B₁

1. Background Information
   1—1. Definition and Classification
   The chemical name of vitamin B₁ is thiamin, and the present DRIs for vitamin B₁ were set as the amount of thiamin hydrochloride; 2-[3-[(4-amino-2-methyl-pyrimidin-5-yl)methyl]-4-methyl]thiazole-5-yl] ethanol. There are 3 types of thiamin hydrochloride: thiamin monophosphate (TMP), thiamin diphosphate (TDP), and thiamin triphosphate (TTP), and their activity is equimolar to that of vitamin B₁.

   1—2. Function
   Vitamin B₁ is involved in the metabolism of glucose and branched-chain amino acids. Insufficient vitamin B₁ intake can cause neuritides or brain damage. Beriberi and Wernicke-Korsakoff syndrome are well-known for being caused by vitamin B₁ deficiency.

   1—3. Digestion, Absorption and Metabolism
   Vitamin B₁ predominantly exists as TDP in living cells in combination with enzyme proteins. TDP is dissociated from proteins through cooking or digestion, and, thereafter, the released TDP undergoes phosphorylation to become thiamin. Thiamin absorption occurs through an active transportation system in the jejunum and ileum. These processes can be affected by the type of food, and other dietary sources. The relative bioavailability of free vitamin B₁ has been reported to be around 60% in the typical Japanese diet(1,2).

2. To Avoid Inadequacy
   2—1. Factors to be Considered in Estimating Requirements
   There should be a difference in the requirement estimation between the calculation using the dietary intake required for recovery from deficiency, and that using the association between dietary intake and urinary excretion of vitamin B₁.

   2—1—1. Estimation of the Dietary Intake Required for Recovery from Deficiency
   It was reported that recovery from vitamin B₁ deficiency (caused by the intake of meals with lower than 0.03 mg/day of vitamin B₁) occurred through an intake of 0.7 mg/day of thiamin hydrochloride, in male Japanese student volunteers(3). Considering the relative bioavailability (60%), an intake of 1.17 mg/day of dietary vitamin B₁ is the yield from 0.7 g/day of thiamin hydrochloride. The experimental meals were set at 2,400 kcal/day, and the requirement of dietary vitamin B₁ intake, in the form of thiamin hydrochloride, was considered to be lower than 0.49/1,000 kcal.
2—1—2. **Estimation of Requirements from Urinary Thiamin Excretion**

Orally administered thiamin is rapidly converted to TDP in the body tissues. Thereafter, excess thiamin is excreted in a free form in the urine. The values obtained through the calculation of excess thiamin may be higher than those required to prevent deficiencies.

The urinary excretion of thiamin sharply increases at an intake of 0.35 mg/1,000 kcal/day of vitamin B₁\(^{(4)}\). This value can be considered the body requirement, as the urinary excretion of thiamin increases sharply when the body’s requirement is met.

2—2. **Method Used to Set the Estimated Average Requirement (EAR) and Recommended Dietary Allowance (RDA)**

These values were determined as amounts per energy intake.

2—2—1. **Adults and Children (EAR and RDA)**

The DRIs adopted the values obtained from the relation of the inflection points of vitamin B₁ intake and vitamin B₁ excretion. As it is a water-soluble vitamin, excess thiamin is excreted in its free form in the urine. Thus, the EAR of vitamin B₁ was determined as the point at which an increase in urine thiamin excretion is observed.

Since vitamin B₁ plays an important role in energy metabolism, these values were determined as amounts per energy intake. From the data of a meta-analysis of 18 countries\(^{(4)}\), the EAR was set at 0.35 mg thiamin (0.45 mg thiamin hydrochloride)/1,000 kcal/day. This value was used as a reference for those aged 1 to 69 years, and the EAR was set using estimated energy requirement values. The RDA was set assuming a coefficient of variation of 20%. No report has stated that the calculation of the values for elderly individuals should be specially considered; thus, the EAR and RDA were determined using the reference value of adults and reference body weight (BW), assuming a coefficient of variation of 10%.

2—2—2. **Additional Amount for Pregnant Women (EAR, RDA)**

The additional amounts were calculated based on the assumption that the requirement of vitamin B₁ increases according to the energy requirement. In other words, the additional EAR and RDA for pregnant women were calculated by multiplying the additional estimated energy requirement values (+50 kcal/day for early-term, +250 kcal/day for mid-term, and +450 kcal/day for late-term pregnancies, at a level 2 physical activity) and the vitamin B₁ EAR reference values (0.45 mg/1,000 kcal), to yield values of 0.023 mg/day for early-term, 0.11 mg/day for mid-term, and 0.20 mg/day for late-term pregnancies. These reference values were calculated solely assuming an increase in energy expenditure, and that energy expenditure differs between individuals. Since metabolism is enhanced during pregnancy, the value for late-term pregnancy (0.2 mg/day) was adopted as the additional amount required for pregnant women, yielding 0.2 mg/day (rounding 0.24 mg/day), determined as the EAR × 1.2.
2—2—3. **Additional Amount for Lactating Women (EAR, RDA)**

The additional amount was calculated based on the assumption that the excreted amount in breast milk is supplemented, using a relative availability of 0.6\(^{(1,2)}\), as follows: \(0.13 \text{ mg/L} \times 0.78 \text{ L/day} / 0.6 = 0.169 \text{ mg/day}\).

The EAR was set at 0.2 \text{ mg/day} by rounding this value.

The additional RDA was determined as the EAR \(\times 1.2\), yielding 0.2 \text{ mg/day} (rounding 0.24 \text{ mg/day}).

2—3. **Method Used to Set Adequate Intake (AI)**

2—3—1. **Infants (AI)**

The average concentration of vitamin B\(_1\) in breast milk is 0.13 \text{ mg/L}\(^{(5–7)}\), and the average milk intake is 0.78 \text{ L/day}\(^{(8,9)}\), representing a daily vitamin B\(_1\) intake of about 0.1 \text{ mg/day}.

This value was set as the AI for infants aged 0 to 5 months.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

- **Expression 1**: \(\text{AI for infants aged 0 to 5 months} \times \left(\frac{\text{reference BW for infants aged 6 to 11 months}}{\text{reference BW for infants aged 0 to 5 months}}\right) 0.75\)
- **Expression 2**: \(\text{EAR for adults aged 18 to 29 years} \times \left(\frac{\text{reference BW for infants aged 6 to 11 months}}{\text{reference BW for adults aged 18 to 29 years}}\right) 0.75 \times (1+ \text{growth factor})\)

Thus, the AI was determined as 0.2 \text{ mg/day} for infants aged 6 to 11 months.

3. **To Avoid Excessive Intake**

3—1. **Dietary Intake**

No regular food includes more than 1 \text{ mg} of vitamin B\(_1\)/100 g. In addition, unfavorable outcomes, as a consequence of the excessive intake of regular food, have not been reported.

3—2. **Method Used to Set the Tolerable Upper Intake level (UL)**

A chronic high dose intake of thiamin (50 \text{ mg/kg BW/day}) has been reported to cause severe toxicity symptoms\(^{(10)}\). For example, an intake of 10 \text{ g} of thiamin hydrochloride every day for 2.5 weeks resulted in headaches, irritability, insomnia, pulsus celer, weakness, contact dermatitis, and itchiness. These symptoms disappeared in 2 days, when the intake was discontinued\(^{(11)}\). Nevertheless, there is insufficient evidence for the determination of the UL.
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Vitamin B2

Vitamin B2

1. Background Information

1—1. Definition and Classification

The chemical name of vitamin B2 is riboflavin, and the present DRIs were determined as the amount of riboflavin: 7,8-dimethyl-10-[(2R,3R,4S)-2,3,4,5-tetrahydroxypentyl]benzog[7]pteridine-2,4(3H,10H)-dione. The activities of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) are equimolar to that of vitamin B2.

1—2. Function

Vitamin B2 functions as coenzymes FMN or FAD, and is involved in several metabolic pathways as well as energy production. Vitamin B2 deficiency causes growth suppression, as the vitamin works in energy metabolism. Its deficiency also causes canker sores, angular cheilitis, tongue inflammation, and seborrheic dermatitis.

1—3. Digestion, Absorption and Metabolism

Riboflavin predominantly exists as FAD or FMN in combination with enzyme proteins. Riboflavin absorption occurs by an active transportation system in the small-intestinal epithelial cells. These processes can be affected by the type of food and other dietary sources. The relative bioavailability of free vitamin B2 has been reported to be around 64% in the typical Japanese diet(1).

2. To Avoid Inadequacy

2—1. Factors to be Considered in Estimating Requirements

There should be a difference in the requirement estimation between the calculation using the dietary intake required for the recovery from deficiency, and that from the association between dietary intake and urinary excretion of vitamin B2.

2—1—1. Estimation of the Dietary Intake Required for Recovery from Deficiency

An experimental study examined vitamin B2 deficiency in 4 Japanese individuals (2 men and 2 women)(12,13). Five to 6 weeks after a vitamin B2-deficient diet was initiated, the participants complained of sore throat, tongue pain, and pain at the edge of the lips, bleeding from the gums and the oral mucosa, aversion to light, or eye strain(13). The recovery experiment led to acute remission after 0.5 mg/day of vitamin B2 was administered for 10 days(12). One female participant consuming 1 mg/day of vitamin B2 reported no complaint. From these results, the vitamin B2 requirement for the prevention of deficiency can be estimated at about 0.5 mg/day. However, considering the relative bioavailability (64%)(1), this value was set as 0.78 mg/day of dietary vitamin B2.
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Vitamin B2

2—1—2. Estimation of Requirements from Urinary Riboflavin Excretion

Usually, only a small amount of riboflavin is excreted in the urine; the level of excretion varies according to the intake of vitamin B2. If the body requirement is met, urinary excretion shows a rapid increase. A gradual increase in the intake of free riboflavin to 1.1 mg/day was shown to result in a rapid rise in urinary excretion. This value can be considered as the body requirement, as the urinary excretion of thiamin increases sharply when the body requirement is met.

2—2. Method Used to Set the EAR and RDA

These values were determined as amounts per energy intake.

2—2—1. Adults and Children (EAR and RDA)

In the determination of the DRIs for vitamin B2, the method used was the same as that for vitamin B1; the values were obtained from inflection point of the relation between vitamin B2 intake and excretion. Thus, the EAR of vitamin B2 was determined as the point at which an increase in urine thiamin excretion was observed. A gradual increase in the intake of free riboflavin to 1.1 mg/day was shown to result in a rapid rise in urinary excretion, in healthy men and women when they received 2,200 kcal/day\(^{(13,14)}\). Based on these results, and the involvement of vitamin B2 in energy metabolism, the EAR was determined as the energy intake/day, i.e., 0.50 mg/1,000 kcal/day for those aged 1-69 years, and the EAR was set using estimated energy requirement values. The RDA was set using a coefficient of variation of 10%.

In terms of elderly individuals, one report stated that the requirement does not differ from that of young adults\(^{(15)}\), and another stated that no special consideration is required. Therefore, the EAR and the RDA were determined using the reference value of adults and reference BW, using a coefficient of variation of 10%.

2—2—2. Additional Amount for Pregnant Women (EAR, RDA)

The additional amounts were calculated based on the assumption that the requirement for vitamin B2 increases according to the estimated energy requirement. In other words, the additional EAR and RDA for pregnant women were calculated by multiplying the additional values of the estimated energy requirement (+50 kcal/day for early-term, +250 kcal/day for mid-term, and +450 kcal/day for late-term pregnancies at level 2 of physical activity), and the vitamin B2 EAR reference values (0.50 mg/1,000 kcal), yielding 0.03 mg/day for first-term, 0.13 mg/day for mid-term, and 0.23 mg/day for late-term pregnancies. These reference values were calculated solely assuming an increase in energy expenditure, and that energy expenditure differs between individuals. Since metabolism is enhanced during pregnancy, the value for late-term pregnancy (0.23 mg/day) was adopted as the additional amount required for pregnant women, yielding 0.3 mg/day (rounding 0.27 mg/day) as the additional RDA, determined as the EAR \(\times 1.2\).
2—3. Additional Amount for Lactating Women (EAR, RDA)

The additional amount was calculated based on the assumption that the excreted amount in breast milk is supplemented, using the relative bioavailability (0.6)\(^{(1,2)}\). The mean concentration of riboflavin in breast milk is 0.40 mg/L, and the average milk volume is 0.78 L/day\(^{(5,7-9)}\). Thus, the additional EAR was 0.5 (rounding 0.52) mg/day. The additional RDA was determined as the EAR × 1.2, yielding 0.6 (rounding 0.62) mg/day.

2—3. Method Used to Set AI

2—3—1. Infants (AI)

The daily vitamin B\(_2\) intake of infants is approximately 0.3 (rounding 0.31) mg/day. This value was set as the AI for infants aged 0 to 5 months.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

Expression 1: the AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75

Expression 2: the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1+ growth factor)

Thus, the AI was determined to be 0.4 mg/day for infants aged 6 to 11 months.

3. To Avoid Excessive Intake

3—1. Dietary Intake

No regular food contains more than 1 mg of vitamin B\(_2\)/100 g. Additionally, no studies have reported the presence of unfavorable outcomes due to an excessive intake of regular foods.

3—2. Method Used to Set the UL

A chronic high intake of riboflavin has not been reported to cause severe toxicity. For example, a daily intake of 400 mg of riboflavin for 3 months\(^{(16)}\), or a single intravenous injection of 11.6 mg of riboflavin\(^{(17)}\) caused no deleterious effects. This may be attributed to the rapid excretion of riboflavin in the urine, and also to limited solubility and reduced absorption at higher doses. Thus, there is no evidence for the determination of the UL. Nevertheless, it has been reported that the maximum absorbable amount of riboflavin in a single dose is 27 mg\(^{(17)}\); therefore, a single intake of excess vitamin B\(_2\) is rarely effective.
1. **Background Information**

1—1. **Definition and Classification**

Niacin activity is predominantly exhibited by nicotinic acid, nicotinamide, and tryptophan. The DRIs for niacin are expressed in niacin equivalents (NEs). The Standard Tables of Food Composition in Japan 2010\(^{(18)}\) lists niacin as the sum of nicotinic acid and nicotinamide, and does not include nicotinamide biosynthesized from tryptophan. Therefore, to calculate the NE in a diet, the amount of nicotinamide biosynthesized from dietary tryptophan should be added to the amount of niacin. The tryptophan to nicotinamide conversion ratio is set at 1/60 on a weight basis. The NE is calculated using the following formula:

\[
\text{Niacin equivalent (mg NE)} = \text{niacin intake (mg)} + \left(\frac{1}{60}\right) \text{tryptophan intake (mg)}
\]

Most protein contains approximately 1% of tryptophan; therefore, the amount of nicotinamide biosynthesized from tryptophan (mg) is estimated as the amount of protein (g) divided by 6.

1—2. **Function**

Nicotinic acid and nicotinamide act as coenzymes for enzymes, such as alcohol dehydrogenase, glucose-6-phosphate dehydrogenase, pyruvate dehydrogenase, and 2-oxoglutarate dehydrogenase, in oxidoreduction reactions, after the conversion of pyridine nucleotide. Niacin is involved in many biological reactions including ATP production, antioxidation via vitamin C or E, as well as fatty acid and steroid synthesis. Nicotinamide adenine dinucleotide (NAD\(^+\)) is used as a substrate of ADP-ribosylation, and is involved in the repair and synthesis of DNA, as well as cell differentiation. Niacin deficiency causes pellagra, in which dermatitis, diarrhea, and neuropsychiatric abnormality are prominent symptoms.

1—3. **Digestion, Absorption, and Metabolism**

In living cells, niacin exists mainly as the cofactor nicotinamide adenine dinucleotide phosphate (NAD(P)), which binds weakly to enzyme proteins. During the cooking and processing of animal and plant foods, NAD(P) is hydrolyzed to nicotinamide and nicotinic acid, respectively. Any remaining NAD(P) is hydrolyzed to nicotinamide in the gastrointestinal tract. Nicotinamide and nicotinic acid are absorbed in the small intestine. Nicotinic acid predominantly binds to complex carbohydrates in cereal grains, and, therefore, has a lower digestibility\(^{(19)}\). The relative availability of dietary niacin to free nicotinamide is approximately 60% in a typical Japanese diet\(^{(1,2)}\).
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Niacin

2. To Avoid Inadequacy

2—1. Factors to be Considered in Estimating Requirements

The conversion ratio of tryptophan to nicotinamide is set at 1/60, on a weight basis. In other words, 60 mg of tryptophan is equimolar to 1 mg of niacin.

2—2. Method Used to Set the EAR and RDA

Niacin relates to energy metabolism, and, therefore, the EAR for niacin is expressed as mg NE/1,000 kcal.

2—2—1. Adults and Children (EAR and RDA)

The requirement was determined from the minimal amount required for the prevention of pellagra. The conversion ratio of tryptophan to nicotinamide is set at 1/60 on a weight basis, according to human studies\(^{(20,21)}\). Niacin relates to energy metabolism, and, therefore, the EAR for niacin is expressed as amount per energy intake. Another human study showed that a urinary N\(^1\)-methylene nicotinamide level of 1.0 mg/day reflects pellagra-like clinical niacin deficiency\(^{(22)}\). An analysis of previous studies showed that the niacin intake equivalent to a urinary N\(^1\)-methylene nicotinamide level of 1.0 mg/day is 4.8 mg NE/1,000 kcal\(^{(20–24)}\). This value was used as the reference for the setting of the EAR for individuals aged 1 to 69 years, and the EAR was determined using estimated energy requirement values. The RDA was determined as the EAR \(\times 1.2\). Based on niacin intake and urinary nicotinamide metabolite data, the niacin activity in older individuals is considered to be the same as that in younger individuals\(^{(25,26)}\). Thus, the EAR and RDA were set using the same calculation method as that used in adults.

2—2—2. Additional Amount for Pregnant Women (EAR, RDA)

There is no evidence for the setting of the EAR using a factorial method, and the additional amounts could be set based on the assumption that the requirement for niacin increases according to the estimated energy requirement; however, the amount of nicotinamide biosynthesized from tryptophan increases during pregnancy, and this compensates for the increase in the niacin requirement\(^{(27)}\). Thus, pregnant women do not require additional niacin intake.

2—2—3. Additional Amount for Lactating Women

The conversion rate of tryptophan to nicotinamide returns to a normal level after delivery\(^{(27)}\), and, therefore, lactating women require additional niacin intake to compensate for the loss of niacin through breast milk. Using 2.0 mg/L as the concentration of breast milk, 0.78 L/day as the average milk volume, and 60% as the relative availability\(^{(1,2)}\), the additional EAR for lactating women was set at 3 mg NE/day (rounding 2.6 mg NE/day). The additional RDA was set at 3 (rounding 3.0) mg NE/day, determined as the EAR \(\times 1.2\).
2—3. Method Used to Set the AI

2—3—1. Infants (AI)

The concentration of niacin in the breast milk of Japanese mothers is 2.0 mg/L\(^{(5-7)}\). Considering an average milk intake of 0.78 L/day\(^{(6,7)}\), the daily nicotinamide intake is 1.56 mg/day. The AI for infants aged 0 to 5 months was set at 2 mg/day. Nicotinamide is unlikely to be biosynthesized from tryptophan at this stage, and, therefore, the AI is expressed in mg/day\(^{(28)}\).

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

**Expression 1:** the AI for infant boys or girls aged 6 to 11 months (extrapolated from the AI of infants) = AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75

**Expression 2:** the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

The means of these extrapolated values were determined for each sex. The average of the obtained values for each sex is 3.1 mg NE/day. Thus, the AI for infants aged 6 to 11 months was set as 3 mg NE/day.

3. To Avoid Excessive Intake

3—1. Dietary Intake

A high amount of nicotinamide is present in animal food, at a maximum of approximately 10 mg/100 g. Nicotinic acid exists in plant food at less than 10 mg/100 g. No studies have reported the presence of unfavorable outcomes due to an excessive intake of regular food.

3—2. Method Used to Set the UL

Nicotinic acid and nicotinamide are often used in niacin supplements and fortified foods. The UL for niacin, therefore, takes into account the nicotinic acid and nicotinamide obtained from supplements and fortified foods. The large doses of nicotinamide and nicotinic acid used to treat patients with type 1 diabetes and dyslipidemia, respectively, may cause gastrointestinal effects such as dyspepsia, diarrhea, and constipation, and also hepatotoxic symptoms such as dysfunction and fulminant hepatitis. According to previous reports\(^{(29-32)}\) the no observed adverse effect levels (NOAELs) for nicotinamide and nicotinic acid were set at 25 mg/kg BW and 6.25 mg/kg BW, respectively. The NOAELs were divided by an uncertainty factor of 5, and the obtained values—5 mg/kg BW and 1.25 mg/kg BW—were set as the ULs for nicotinamide and nicotinic acid, respectively. The ULs were determined using these values, according to age and sex group. A pharmacological dose of nicotinic acid has the transient vasodilatory effect of flushing (reddening of the skin), but does not cause adverse health effects. Thus, it is not appropriate to use flushing as symptom for the setting of the UL for nicotinic acid.
**Vitamin B₆**

1. **Background Information**
   1—1. **Definition and Classification**
   
   The chemical substances possessing vitamin B₆ activity are pyridoxine (PN), pyridoxal (PL), and pyridoxamine (PM), and their respective phosphorylated forms. The phosphorylated forms—pyridoxine-5-phosphate (PNP), pyridoxal-5-phosphate (PLP) and pyridoxamine 5-phosphate (PMP)—have an activity that is equimolar to that of vitamin B₆. The current DRIs were determined as the amount of pyridoxine.

   1—2. **Function**
   
   Vitamin B₆ functions as the coenzyme PLP, and is involved in transamination reaction, decarboxylation, and racemization reaction. Vitamin B₆ is important for the maintenance of immune systems, as vitamin B₆ deficiency decreases the rate of the conversion of linoleic acid to arachidonic acid. Deficiency causes pellagra-like symptoms, seborrheic dermatitis, tongue inflammation, angular cheilitis, or hypolymphemia.

1—3. **Digestion, Absorption and Metabolism**

   Vitamin B₆ predominantly exists as PLP or PMP, in combination with enzyme proteins. Once PLP and PMP dissociate, they are absorbed as PL or PM. Living plant cells contain pyridoxine-5’β-glucoside (PNG). PNG is absorbed as PN in humans, and the relative bioavailability of PNG has been estimated to be 50% (33). The digestion processes associated with this vitamin are affected by the type of food and other dietary sources. The relative bioavailability of free vitamin B₆ has been reported to be 75% in the US (34), and 73% in the typical Japanese diet (1).

2. **To Avoid Inadequacy**
   2—1. **Method Used to Set the EAR and RDA**

   These values were determined as amounts per protein intake.

   2—1—1. **Adults and Children (EAR and RDA)**

   Vitamin B₆ is involved in the catabolism of amino acids and formation of bioactive amines, including some neurotransmitters. The plasma PLP concentration has been reported to reflect the body store of vitamin B₆ (35). A low plasma PLP concentration is associated with electroencephalographic changes in young, non-pregnant women (36). Furthermore, a plasma PLP concentration of 30 nmol/L was required to alleviate vitamin B₆ deficiency-induced disorders (37). The EAR for vitamin B₆ was based on the amount of vitamin B₆ required for a maintenance of a plasma PLP level of 30 nmol/L.

   The vitamin B₆ requirement increases as the protein intake increases, and the plasma
Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Vitamin B₆

PLP concentration correlates well with vitamin B₆ intake per protein intake\(^{(38)}\). Thus, 0.014 mg pyridoxine/g protein was estimated as the concentration required to maintain a plasma PLP concentration of 30 nmol/L. The EAR reference value was determined (0.014/0.73) using a relative bioavailability of 73\%\(^{(1)}\). The EARs were calculated by multiplying this value by the RDAs of protein. The RDA was calculated as the EAR × 1.2. To obtain the daily requirement of vitamin B₆, the EAR of vitamin B₆ was multiplied by the RDA of protein.

In terms of elderly individuals, a previous report stated that plasma PLP levels decrease with increasing age\(^{(39)}\); however, due to a lack of data, the EAR and the RDA were determined using the same method as that used in adults.

2—1—2. Additional Amount for Pregnant Women (EAR, RDA)

The plasma PLP concentration reportedly decreases during pregnancy\(^{(40–52)}\). The additional amount required depends on whether plasma PLP should be maintained at levels that are similar to those in non-pregnant women or those in the first-stage of pregnancy, or taking into consideration if the aforementioned decrease in the PLP concentration occurs as a common physiological response to pregnancy.

The previous DRIs adopted the former method, and set the additional amounts of EAR and RDA for pregnant women using the method used in the US-Canada DRIs\(^{(38)}\), and the relative bioavailability in Japan\(^{(1)}\). However, while no study has reported on vitamin B₆ deficiency in this context, the vitamin B₆ intake of pregnant Japanese pregnant women does not exceed the previous EAR of 1.7 mg/day. Therefore, the additional amount of vitamin B₆ required was reconsidered.

Although vitamin B₆ involves the production of tryptophan metabolites, the proportion of some of these metabolites increases, rather than decreases, under conditions of vitamin B₆ insufficiency. Moreover, their effects on pregnant women and fetuses remain unclear.

The decrease in the plasma PLP level during the late term of pregnancy is considered to be caused by the increased requirement of the fetus\(^{(49)}\). This decrease is considered a result of increased placental PL transportation due to the elevated PLP→PL reaction rate that is caused by elevated serum alkaline phosphatase levels in mothers, so as to provide vitamin B₆ to the fetus\(^{(42,47,51,52)}\).

During the late stage of pregnancy, to maintain 30 nmol/L of plasma PLP (at a level which is equal to that of women who are not pregnant), an additional 4 to 10 mg/day of pyridoxine is needed\(^{(40)(47)(52)(44)}\). However, these amounts are quite different from the potential intakes for the Japanese population, based on the current intake. Lui et al. recommended maintaining a plasma PLP level of 20 nmol/L to prevent vitamin B₆ deficiency\(^{(35)}\). Abnormal electroencephalograms have been observed at plasma PLP levels lower than 10 nmol/L in non-pregnant women\(^{(36)}\). Another study examined pregnant Japanese women, and reported their mid-term and late-term pregnancy plasma PLP levels (mean±standard deviation) to be 23.3 ± 16.7 nmol/L and 18.3 ± 12.5 nmol/L, respectively\(^{(53)}\). Thus, the additional amount of vitamin
B₆ required would be low, considering the enhanced vitamin B₆ metabolism during pregnancy. However, the requirement for protein increases according to the body protein storage required during pregnancy, enhancing amino acid metabolism.

From these findings, the additional EAR was determined considering the body protein storage for the placenta and fetus. In other words, the value was calculated based on the EAR reference of pyridoxine for non-pregnant women (0.014 mg/ protein g) and body protein storage during pregnancy, using the relative bioavailability. During pregnancy, the efficiency of various nutrients increases; however, due to a lack of data, the relative bioavailability was set as 73%(1). The additional EAR was calculated as follows:

**Early-term pregnancy**
\[
\frac{0.014 \text{ mg/g protein } \times 0 \text{ g/day}}{0.73} = 0 \text{ mg/day}
\]

**Mid-term pregnancy**
\[
\frac{0.014 \text{ mg/g protein } \times 1.94 \text{ g/day}}{0.73} = 0.027 \text{ mg/day}
\]

**Late-term pregnancy**
\[
\frac{0.014 \text{ mg/g protein } \times 8.16 \text{ g/day}}{0.73} = 0.114 \text{ mg/day}
\]

The RDAs were determined as these values × 1.2, yielding 0 mg, 0.044 mg and 0.187 mg for early-term, mid-term, and late-term pregnancies, respectively.

These values were calculated solely assuming an increase in the amount of protein required, and that requirement differs between individuals. Since metabolism is enhanced during pregnancy, the value for late-term pregnancy (0.156 mg/day) was adopted as the additional amount required by pregnant women, yielding 0.2 mg/day (rounding 0.156 mg/day). The additional RDA was calculated as the additional EAR × 1.2, yielding 0.2 mg/day (rounding 0.187 mg/day).

### 2—1—3. Additional Amount for Lactating Women

The additional EAR for pregnant women was calculated based on the mean concentration of vitamin B₆ in breast milk (0.25 mg/L)(54,55), the average milk volume (0.78 L/day)(8,9), and the relative bioavailability (73%)(1), i.e., 0.3 mg/day (rounding 0.267 mg/day). The additional RDA was calculated as the additional EAR × 1.2.

### 2—2. Method Used to Set AI

#### 2—2—1. Infants (AI)

For infants aged 0 to 5 months, the vitamin B₆ intake is approximately 0.2 mg/day (rounding 0.195 mg/day) based on the mean concentration of vitamin B₆ in breast milk (0.25 mg/L)(54,55) and the average milk intake (0.78 L/day)(8,9). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

**Expression 1:** the AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Vitamin B₆

Expression 2: the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

Thus, the AI was determined to be 0.3 mg/day for infants aged 6 to 11 months.

3. To Avoid Excessive Intake
   3—1. Dietary Intake
       No regular food contains more than 1 mg of vitamin B₆/100 g. No reports have suggested the development of unfavorable outcomes due to the excessive intake of regular food.

3—2. Method Used to Set the UL
       A high intake of pyridoxine over a course of several months was shown to result in sensory neuropathy(56). This symptom was used as a criterion for the estimation of the UL for pyridoxine. In contrast, the administration of 100-300 mg pyridoxine/day over a period of 4 months did not cause sensory neuropathy in 24 patients with carpal tunnel syndrome(57). Based on these data, the NOAEL was set at 300 mg/day. Assuming an uncertainty factor of 5, the UL for pyridoxine was set at 60 mg/day-0.86 mg/kg BW. The UL for each age group was obtained by multiplying the UL by the reference BW.
Vitamin B12

1. Background Information
2. Definition and Classification

Vitamin B12 is a cobamide, and there are various B12 compounds with different upper ligands, such as methylcobalamin, sulfitecobalamin, and cyanocobalamin. The DRIs for vitamin B12 were set as the amount of cyanocobalamin.

1—2. Function

Vitamin B12 is a cofactor for methionine synthetase and L-methylmalonyl-coenzyme A mutase. Vitamin B12 deficiency causes megaloblastic anemia, white-matter deficit in the spinal cord and brain, and peripheral neuropathy.

1—3. Digestion, Absorption and Metabolism

Food-bound vitamin B12 is dissociated from proteins in the presence of acid and pepsin. The released vitamin B12 then binds to the haptocorrins secreted by the salivary glands. Haptocorrins are partially degraded in the duodenum, releasing vitamin B12, which then binds with intrinsic factor. The intrinsic factor-vitamin B12 complex enters the enterocyte after binding with the receptors in the ileal mucosa. The dietary absorption was reported to be around 50% in healthy participants (58,59).

2. To Avoid Inadequacy

2—1. Factors to be Considered in Estimating Requirements

The DRIs considered the values required for the treatment of anemia in pernicious anemia patients without intrinsic factors.

2—2. Method Used to Set the EAR and RDA

2—2—1. Adults and Children (EAR and RDA)

It is not possible to determine the EAR of vitamin B12 for healthy adults, because of the intrinsic-factor-mediated B12 gastrointestinal absorption system and/or the substantial enterohepatic vitamin B12 circulation. Thus, the EAR for adults was estimated based on clinical data from vitamin B12-deficient patients with pernicious anemia, that examined the amount of vitamin B12 required for the maintenance of an adequate hematological status (mean corpuscular volume < 101 fL) and serum vitamin B12 level (100 pmol/L or more). Studies reported that an intramuscular injection with varying concentrations (0.1–10 μg/day) of vitamin B12 showed an increase in the capacity of erythrocyte production at 0.1 μg/day (44), indicating the maximum capacity at 0.5 to 1.0 μg/day (60). Another study reported that an improvement in the mean corpuscular volume was observed at 1.4 μg/day (range 0.5 to 4.0 μg/day) of vitamin B12 injection in half of the patients with pernicious anemia (61). These data suggest an average
intramuscular requirement of 1.5 mg/day for the maintenance of an adequate hematological status.

Vitamin B\textsubscript{12}-deficient patients with pernicious anemia cannot reabsorb vitamin B\textsubscript{12} (0.5 μg/day) from the bile, due to the lack of an intrinsic-factor-mediated vitamin B\textsubscript{12} absorption system. Thus, under normal physiological conditions, an average intake of 1.0 μg/d is required to compensate for the estimated extra losses of biliary vitamin B\textsubscript{12} (0.5 μg/day) from the average intramuscular requirement (1.5 μg/day). Adjusting for this value with a 50% absorption rate of dietary vitamin B\textsubscript{12}, the EAR was set at 2.0 μg/day for adults. The RDA was calculated as 2.4 mg/day, by multiplying the EAR and 1.2.

Although serum vitamin B\textsubscript{12} levels are known to be higher in women than men\textsuperscript{(62–64)}, data on this are insufficient. Therefore, the same values were adopted for both sexes.

The EAR for children was calculated from the EAR for adults aged 18 to 29 years, using the following equation for body surface area, at each age:

\[(\text{Reference BW at each age/reference BW of adults aged 18 to 29 years}) \times 0.75 \times (1 + \text{growth factor}).\]

The EARs and DRIs for those aged over 50 years were set at values that were identical to those set for adults aged 18 to 49 years, due to a lack of detailed information on the decrease in vitamin B\textsubscript{12} absorption in elderly individuals\textsuperscript{(65,66)}.

2—2—2. Additional Amount for Pregnant Women (EAR, RDA)

The human fetus is estimated to accumulate 0.1 to 0.2 μg/day of vitamin B\textsubscript{12}\textsuperscript{(67,68)}. Using the median (0.15 μg/day) of the fetal deposition, and the 50% absorption rate of dietary vitamin B\textsubscript{12} in healthy adults, the additional EAR for pregnant women was set at 0.3 μg/day. The additional RDA was estimated as 0.4 μg/day (rounding 0.36 μg/d) by multiplying the additional EAR and 1.2.

2—2—3. Additional Amount for Lactating Women

Using the average vitamin B\textsubscript{12} concentration and secretion of breast milk, and the 50% absorption rate of dietary vitamin B\textsubscript{12} in healthy adults (0.45 μg/L \times 0.78 L/day/0.5), the additional EAR for lactating women was set at 0.7 μg/day (rounding 0.702 μg/d). The additional RDA was calculated as 0.8 μg/day (rounding 0.84 μg/d) by multiplying the additional EAR and 1.2.

2—3. Method Used to Set AI

2—3—1. Infants (AI)

For infants aged 0 to 5 months, the mean concentration of vitamin B\textsubscript{12} in breast milk is 0.45 μg/L\textsuperscript{(6,7,69)}. The average milk volume is 0.78 L/d\textsuperscript{(8,9)}, representing a daily vitamin B\textsubscript{12} intake of about 0.4 μg/day (rounding 0.35 μg/day). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values
from the following 2 expressions:

Expression 1: the AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75

Expression 2: the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

Thus, the AI was determined to be 0.5 μg/day for infants aged 6 to 11 months.

3. To Avoid Excessive Intake

3—1. Dietary Intake

Vitamin B_{12} absorption is regulated by the intrinsic factor secreted by the stomach in the intestinal absorption system. No reports till date have suggested the presence of unfavorable outcomes due to the excessive intake of regular foods.

3—2. Method Used to Set the UL

Vitamin B_{12} cannot be absorbed when its intake is excessive, and the intrinsic-factor-regulating absorption system is saturated\(^{(61,70)}\). The oral administration of substantial amounts (500 μg) of vitamin B\(_{12}\) was shown to result in only about 1% absorption in the intestine\(^{(61)}\). No harmful effect was observed even when a mega dose (2.5 mg) of vitamin B\(_{12}\) was administrated parenterally\(^{(71)}\). Thus, the UL was not determined for vitamin B\(_{12}\).
Folate

1. **Background Information**

1—1. **Definition and Classification**

The basic skeleton of folate is pteroylmonoglutamate, which comprises "p"-aminobenzoic acid with pterin rings and glutamate. Folate naturally occurs in combination with 1 or more molecules of glutamate (γ-binding).

In its narrowest sense, folate is referred to as pteroylmonoglutamate. In a broader sense, it includes coenzyme species in their reduced form, as well as single-carbon compounds and their polyglutamate forms. The present DRIs used the broader definition, as equivalents of pteroylmonoglutamate, in accordance with The Standard Tables of Food Composition 2010.

1—2. **Function**

Folate functions as a coenzyme in single-carbon transfers, in the metabolism of nucleic and amino acids. Folate deficiency causes megaloblastic anemia. Folate deficiency in mothers can lead to fetal neural tube defects (NTDs) and anencephalia.

1—3. **Digestion, Absorption and Metabolism**

Most naturally occurring folates (food folates) are pteroylpolyglutamates, the activities of which are more easily lost during cooking than those of pteroylmonoglutamates--the form used in vitamin supplements. Pteroylpolyglutamates are hydrolyzed to monoglutamate forms in the gut before absorption across the intestinal mucosa. The digestion processes can be affected by the type of food and other dietary sources. The relative bioavailability of food folate is reported to be 25-81% that of pteroylmonoglutamate(72–74). The relative bioavailability of free-pteroylmonoglutamate is reported to be 50% in the typical Japanese diet(2).

2. **To Avoid Inadequacy**

2—1. **Factors to be Considered in Estimating Requirements**

The relative bioavailability of dietary folate depends on its food sources, and is influenced by other dietary intakes. Naturally occurring folates include various reduced forms, which are a combination of polyglutamate chains and 1 carbon fragment. Polyglutamate is hydrolyzed by conjugase in the jejunum, and is converted to monoglutamate. This is then actively absorbed by specific transporters, and is present in the mucosal cell in its monoglutamate form. Conjugase is an enzyme that comprises zinc as a prosthetic group. It is well-known that orange juice and banana contain the conjugase activity inhibitor(75).
2—2. Method Used to Set the EAR and RDA

2—2—1. Adults and Children (EAR and RDA)

The concentrations of red blood cell folate (300 nmol/L) and plasma total homocysteine (14 μmol/L) were applied as biomarkers to reflect the middle- to long-term folate nutritional status (76–79). The EAR for adults aged 18 to 29 years old was estimated as 200 μg/day. The RDA was calculated as 240 μg/day, by multiplying the EAR and 1.2. The lower value was adopted if the values for the men and women, in each group, were different.

The EAR for children was calculated from the EAR for adults (200 μg/day), using the following equation for body surface area, in each age group:

(Reference BW at each age/reference BW of those aged 18 to 29 years) 0.75 × (1 + growth factor).

For adults aged over 50 years old, folate bioavailability was estimated to be equivalent to that of younger adults (79); therefore, the same value as that of adults aged 18 to 29 years old was adopted.

2—2—2. Additional Amount for Pregnant Women (EAR, RDA)

Women with macrocytic anemia during pregnancy recover naturally after delivery (78), indicating a considerable increase in the demand for folate during pregnancy. The addition of 100 μg/day of pteroylmonoglutamate to a diet adequate in food folate has been reported to result in adequate levels of red cell folate (80,81). Thus, this value was set as the additional EAR (200 μg/day; 100/bioavailability rate 0.5 (2,72)). The additional RDA was calculated by multiplying the additional EAR and 1.2, yielding 240 μg/day.

2—2—3. Additional Amount for Lactating Women

The additional EAR for pregnant women was calculated based on the mean concentration of folate in breast milk (54 μg/L (5–7)), the average milk volume (0.78 L/day) (8,9), and the relative bioavailability (50%) (2,72), yielding 80 μg/day (rounding 84 μg/day). The additional RDA was calculated by multiplying the additional EAR and 1.2, yielding 100 μg/day.

2—3. Method Used to Set AI

2—3—1. Infants (AI)

For infants aged 0 to 5 months, the mean concentration of vitamin folate in breast milk is 54 μg/L (5–7). The average milk intake is 0.78 L/day (8,9), representing a daily folate intake of 40 μg/day (rounding 42 μg/day). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

Expression 1: AI for infants aged 6 to 11 months (extrapolated from the AI for infants) = AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75
**Expression 2: the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)**

Thus, the AI was determined to be 60 μg/day for infants aged 6 to 11 months.

3. **To Avoid Excessive Intake**

3—1. **Dietary Intake**

No regular food contains more than 300 μg of folate/100 g except for liver. No study till date has reported the presence of unfavorable outcomes due to an excessive intake of regular food.

3—2. **Method Used to Set the Tolerable Upper Intake level**

In the United States (US), adverse health effects such as the masking of pernicious anemia and neurological damage resulting from elevated serum folate levels, caused by the intake of folic acid-supplemented foods, have been reported(82). This masking of pernicious anemia(83–86) is the biggest factor involved in the setting of the UL for folate intake. When individuals with insufficient vitamin B₁₂ levels consume large amounts of pteroylmonoglutamate, the development of pernicious anemia is masked; in addition, it also leads to the progression of more severe disease as well as posterior spinal degeneration(83–86).

These adverse effects may be induced by the dihydropteroylmonoglutamate derived from pteroylmonoglutamate, which inhibits the activities of thymidylate synthase(87), phosphoribosylaminoimidazolecarboxamide transformylase(88), and 5,10-methylenetetrahydrogenase(89). Thus, consuming excessive amounts of pteroylmonoglutamate may inhibit the single-carbon transfer pathways of folate metabolism.

Pteroylmonoglutamate intake is now common, as folate supplementation is recommended before or in the early term of pregnancy, for the prevention of NTDs. However, while supplementation may prevent NTDs, unfavorable outcomes (neurological damage) have been reported. Therefore, the UL for pteroylmonoglutamate should be determined.

The UL of folate intake was determined according to the US-Canada DRIs(90). Women of reproductive age who were administered 0.36-5 mg/day of pteroylmonoglutamate from the preconception period till the gestational age of 3 months had no serious side effects(90). Based on this finding, the adverse effect level was estimated to be 5 mg/day, equivalent to 88 mg/kg BW/day using the reference BW of women aged 19 to 30 years(91). The UL reference was estimated as 18 μg/kg BW/day, by dividing the value by an uncertainty factor of 5. The UL was determined using the reference value and reference BW in each age group. Related studies on this topic have been limited to those on women; therefore, the UL for men was the same as that for women.
3—3. **Additional Concerns regarding Women of Reproductive Age**

Fetal NTDs are disorders pertaining to the closure of the neural tube (which occurs approximately 28 days after conception), and are clinically diagnosed as anencephaly, spina bifida, and myelomeningocele. Abundant evidence suggests that the preconceptual intake of pteroylmonoglutamate decreases the risk of fetal NTDs\(^{(92–102)}\). Genetic polymorphisms of the enzymes related to folate metabolism (e.g., methylene tetrahydrofolate reductase) may be associated with NTD risk\(^{(92–102)}\).

Other congenital disorders that can be avoided through the administration of pteroylmonoglutamate are cleft lip/palate\(^{(103,104)}\) and congenital heart disease\(^{(104)}\). Thus, maintaining an adequate maternal folate status is essential for the prevention of NTDs. To estimate the minimum effective dose for the risk reduction of NTDs, the lowest reported preconception dose (0.36 mg/day; at 0.36 to 5 mg/day for over 3 months\(^{(92–102)}\)) was applied. This value was rounded to 0.4 mg/day, i.e., a dietary folate equivalent of 800 mg/day.

4. **For the Prevention of the Development and Progression of LRDs**

4—1. **The Association with LRDs**

4—1—1. **Prevention of Disease Development**

4—1—1—1. **The Association between Plasma Homocysteine Levels and Cardiovascular or Cerebrovascular Diseases**

Higher folate intakes have been reported to be associated with a decreased risk of stroke or heart disease\(^{(105,106)}\). Several randomized controlled trials have investigated the preventive effect of folic acid, but the results are inconsistent\(^{(107,108)}\). Inconsistencies in the intervention and observation, and the results of each of those studies must be further studied. The amount of vitamin consumed exceeded the possible dietary intake in the intervention studies; in addition, other types of vitamin B or various polyphenols may have influenced the results of the observational studies.

4—1—1—2. **Association between Folate Intake and Cancer**

Previous epidemiological studies have shown that the intake of pteroylmonoglutamate during pregnancy protects against the development of NTDs; however, the risk of cancer is considered to increase with intake. A meta-analysis of approximately 50,000 individuals showed that the risk neither increased nor decreased with long-term pteroylmonoglutamate supplementation\(^{(109)}\).

4—1—2. **Prevention of Disease Progression**

No data were available in this regard.

4—2. **Tentative Dietary Goal for Preventing LRDs**

The DG was not determined due to a lack of data.
Pantothenic acid

1. Background Information

1—1. Definition and Classification

Pantothenic acid exists mainly as coenzyme A (CoA) derivatives, acetyl CoA, acyl CoA, acyl-carrier protein (ACP) and 4-phosphopantetheine, the activities of which are equimolar to that of pantothenic acid. The present DRIs were determined as the amount of pantothenic acid.

1—2. Function

Pantothenic acid functions as a component of CoA and phosphopantetheine, which are involved in carbohydrate and fatty acid metabolism. Pantothenic acid is widely distributed in foods, and cases of deficiency are rare.

1—3. Digestion, Absorption and Metabolism

CoA in the diet is hydrolyzed in the intestinal lumen to dephospho-CoA and pantetheine, and these are hydrolyzed to pantothenic acid in its absorbable form. The digestion of this vitamin is affected by the type of food, and other dietary sources. The relative bioavailability of pantothenic acid is reported as 70% in the typical Japanese diet(1,2).

2. To Avoid Inadequacy

2—1. Factors to be Considered in Estimating Requirements

Pantothenic acid is involved in fatty acid metabolism.

2—2. Method Used to Set AI

2—2—1. Adults and Children (AI)

There is no evidence for the setting of the EAR for pantothenic acid, as there are no reports on this vitamin’s deficiency in humans. Thus, we estimated the AIs based on the Japanese intake. According to the National Health and Nutrition Survey (NHNS) 2010 and 2011(110), the median dietary pantothenic acid intake among adults and adolescents is 3-7 mg/day. In another dietary assessment study, the mean pantothenic acid intake was reported to be 4.6 mg/day in young Japanese women(111). A study on Japanese individuals aged 32-76 years reported that the mean intakes were 7 mg/day and 6 mg/day in the men and women, respectively(112). There is no evidence that these intake levels lead to pantothenic acid deficiency. Thus, the AIs were adopted from the median dietary pantothenic acid intake determined in the NHNS 2010 and 2011, corresponding to participants’ sex and age. The AIs for elderly individuals were set as the same median value, as there are no data indicating the need for special consideration in terms of pantothenic acid nutrition in this population.
2—2—2. Infants (AI)

For infants aged 0 to 5 months, the mean concentration of pantothenic acid in breast milk is 5.0 mg/L\(^5,7\). The average milk volume is 0.78 L/day\(^8,9\), representing a daily pantothenic acid intake of 4.0 mg/day (rounding 3.9 mg/day). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:

Expression 1: the AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75
Expression 2: the AI for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

Thus, the AI was determined to be 3 mg/day for infants aged 6 to 11 months.

2—2—3. Pregnant Women (AI)

There is no evidence for the determination of the additional pantothenic acid amount for pregnant women by the factorial method. Moreover, there is no indication that the pantothenic acid requirement rises with increases in the energy requirement during pregnancy. Thus, the pantothenic acid intake for pregnant women was estimated using the median of the dietary pantothenic acid intake determined in the NHNS 2010 and 2011\(^113\). The AI for pregnant women was set at 5 mg/day.

2—2—4. Lactating Women (AI)

For pantothenic acid, the estimated AIs are in excess of the pantothenic acid requirement. Thus, the pantothenic acid intakes for lactating women are estimated using the median dietary pantothenic acid intake determined in the NHNS 2010 and 2011\(^113\). The AI for lactating women was set at 5 mg/day.

3. To Avoid Excessive Intake

3—1. Dietary Intake

No regular food contains more than 5 mg of pantothenic acid/100 g except for liver. No study till date has reported unfavorable outcomes due to the excessive intake of regular food.

3—2. Method Used to Set the UL

A pharmacological dose of pantothenic acid, administered over 3 months, in combination with nicotinamide, ascorbic acid, and pyridoxine, was reported to cause adverse effects such as nausea, poor appetite, and abdominal pain in children\(^114\). However, there are no reports stating that a pharmacological dose of pantothenic acid causes adverse health effects. Thus, the UL for pantothenic acid was not set at present.
4. For the Prevention of the Development and Progression of LRDs

4—1. The Association with LRDs

No data were available in this context. The DG was not determined due to a lack of data.
Biotin

1. Background Information

1—1. Definition and Classification

Biotin is a compound formally known as 5-[(3aS, 4S, 6aR)-2-oxysohexyshydro-1H-cheno[3, 4d]-imidazole-4-yl] pentatonic acid, and only its d-isomer shows physiological activity. The present DRIs were determined as the amount of biotin.

1—2. Function

Biotin functions as a coenzyme in bicarbonate-dependent carboxylation reactions. Biotin deficiency can cause immune deficiency disorders such as rheumatism, Sjogren's syndrome and Crohn's disease. Insufficient biotin intake can also cause various symptoms such as dermatitis, atrophic gingivitis, lack of appetite, nausea, and facial pallor.

1—3. Digestion, Absorption and Metabolism

Biotin predominantly exists as protein-bound forms in food. Released biotin is absorbed mainly from the jejunum. The digestion of this vitamin can be affected by the type of food, and other dietary sources. The relative bioavailability of free biotin has been reported to be 80% in the typical Japanese diet\(^2\).

2. To Avoid Inadequacy

2—1. Method Used to Set AI

2—1—1. Adults and Children (AI)

There are currently no data on which the EAR for adults can be based. The average daily biotin intake among Americans is 35.5 μg/day\(^{115}\). The average daily biotin intakes among Japanese individuals are 45.1 μg/day\(^{116}\) and 60.7 μg/day\(^{117}\). According to the Standard Tables of Food Composition in Japan 2010\(^{18}\) that listed biotin for the first time, the biotin intakes are approximately 30 μg/day\(^{118}\) and 50 μg/day\(^{119}\). However, in many standard tables, the biotin component values of several foods are still not listed. Thus, the AIs were set based on the average dietary biotin intakes for adults from the previous total dietary assessment methods, i.e., 50 μg/day for adults aged 18 to 69 years.

The AI for children was calculated from the AI for adults (50 μg/day), using the following equation:

\[
\text{The AI for adults aged 18 to 29 years} \times (\text{reference BW for children/reference BW for adults aged 18 to 29 years}) \times 0.75 \times (1 + \text{growth factor}).
\]

Few studies have investigated the biotin requirements of elderly individuals. There are no data indicating that the biotin requirements of healthy individuals, aged over 70 years, differ from those of young adults. Thus, the AI for those aged over 70 years is the same as that for adults aged 18 to 29 years.
There were insufficient data to allow for the differences in requirements to be discerned between men and women, across all age groups. The lower value was adopted if the values of the men and women varied, in each age group.

2—1—2. Infants (AI)

For infants aged 0 to 5 months, the mean concentration of biotin in breast milk is 5 μg/L\(^{(6,7,120,121)}\). The average milk intake is 0.78 L/day\(^{(8,9)}\), representing a daily biotin intake of 4.0 μg/day (rounding 3.9 μg/day). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values from following 2 expressions:

Expression 1: The AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75
Expression 2: the AI for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

Thus, the AI was determined to be 10 μg/day for infants aged 6 to 11 months.

2—1—3. Pregnant Women (AI)

Pregnant women have reduced serum biotin concentrations, as well as reduced biotin excretion in the urine. In contrast, the urinary excretion of organic acids such as 3-hydroxyisovaleric acid increases during late pregnancy\(^{(122)}\). These findings indicate that pregnancy increases biotin requirements. However, there are no data on the additional amount required by pregnant women. Thus, the AI for pregnant women was set at the AI of non-pregnant women.

2—1—4. Lactating Women (AI)

The amount of biotin required during lactation should be calculated from the differences in the biotin requirements of lactating and non-lactating women of a similar age. However, no such data are available. Thus, the AI for lactating women was set at the AI of non-lactating women.

3. To Avoid Excessive Intake

3—1. Dietary Intake

No regular food contains more than several dozen μg of folate/100 g except for liver. No study till date has reported unfavorable outcomes due to an excessive intake of regular food.

3—2. Method Used to Set the UL

There was insufficient evidence for the determination of the UL for healthy individuals. Excessive biotin intake of 200 mg/day is not associated with adverse effects, even in patients with biotin-responsive inborn errors of metabolism\(^{(114)}\).
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Biotin

4. For the Prevention of the Development and Progression of LRDs
4—1. The Association with LRDs

No relevant data were available. The DG was not determined due to a lack of data.
Vitamin C

1. Background Information

1—1. Definition and Classification

The present DRIs were determined as the amount of ascorbic acid. Vitamin C (ascorbic acid) is a compound of (R)-3, 4-Dihydroxy-5-[(S)-1, 2-Dihydroxyethyl] furan-2(5H)-one, commonly known as L-ascorbic acid or ascorbic acid. Vitamin C freely exists as L-ascorbic acid in its reduced form, or L-dehydroascorbic acid in its oxidized form.

1—2. Function

Vitamin C is essential for the biosynthesis of collagen, skin, and cells. Vitamin C deficiency causes scurvy. Vitamin C also has antioxidant functions.

1—3. Digestion, Absorption and Metabolism

Vitamin C is transported to the blood after intestinal absorption. The digestion processes related to this vitamin can be affected by the type of food, and other dietary sources. The relative bioavailability of vitamin C is 90% up to an intake of 200 mg/day, and less than 50% at more than 1 g/day, pointing to differences between dietary intake and intake in the form of supplements\(^{123}\). The body’s vitamin C level is maintained through various mechanisms, and the plasma concentration is saturated at an intake of about 400 mg/day\(^{124,125}\).

2. To Avoid Inadequacy

2—1. Factors to be Considered in Estimating Requirements

The demand is higher for smokers and passive smokers than non-smokers\(^{121,126–128}\). Compared to others in the same age group, the vitamin C intakes of these individuals must be higher amounts than the RDA.

2—2. Method Used to Set the EAR and RDA

2—2—1. Adults and Children (EAR and RDA)

Severe vitamin C deficiency results in scurvy, which may be preventable by an ascorbic acid intake of 6-12 mg/day\(^{129,130}\). Optimal antioxidant activity in the plasma, and the prevention of cardiovascular disease are achieved at a plasma ascorbic acid concentration of 50 μmol/L\(^{131}\).

A meta-analysis of 36 studies (participants’ age: 15 to 96 years) that examined the association between vitamin C intake and plasma concentration reported that an vitamin C intake of 83.4 mg/day was necessary for the plasma vitamin C level to be maintained at 50 μmol/L\(^{125,132}\). From these findings, the EAR for adults aged 18 to 29 years was determined to be 83.4 mg/day; this method was preferred for the setting of a value for the prevention of scurvy.
The RDA was calculated as the EAR × 1.2. The differences in the requirements between sexes were not considered\(^{(125)}\).

The EAR and RDA for children was calculated from the EAR and RDA for adults aged 18 to 29 years, using the following equation:

$$\text{EAR (RDA) for adults aged 18 to 29 years} \times \left(\frac{\text{reference BW for children}}{\text{reference BW for adults aged 18 to 29 years}}\right) 0.75 \times (1 + \text{growth factor}).$$

The lower value was adopted if the values differed between the men and women, in each age group.

The meta-analysis stated above conducted a separate analysis using studies examining individuals aged 15-65 years, and those examining adults aged 60-96 years. The intake required for the achievement of the same plasma vitamin C level was higher in the latter analysis\(^{(132)}\). Therefore, elderly individuals may need to consume a higher amount of vitamin C; however, it was difficult to set a value specifically for this age group. Thus, the EAR and RDA values were adopted from those applicable to adults aged 18 to 69 years.

In a vitamin C depletion–repletion study conducted in men and women, the excretion of unmetabolized ascorbic acid into the urine was not detectable at an intake of 50 to 60 mg/day, but was detectable at an intake of 100 mg/day, under conditions in which the leukocyte vitamin C, as an indicator of body store, was saturated\(^{(124,125)}\). This finding supports the setting of an RDA value of 100 mg/day.

2—2—2. Additional Amount for Pregnant Women (EAR, RDA)

The additional amounts were calculated based on the intake of vitamin C required to prevent infant scurvy. Thus, the additional EAR was set at 10 mg/day\(^{(133)}\). The additional RDA was set by assuming a coefficient of 1.2, yielding 10 mg/day (rounding 12 mg/day).

2—2—3. Additional Amount for Lactating Women (EAR, RDA)

The additional EAR for lactating women was calculated based on the mean concentration of vitamin C in breast milk (50 mg/L\(^{(6,7,69)}\)), the average milk volume (0.78 L/day)\(^{(8,9)}\), and the relative bioavailability (100%)\(^{(1)}\), yielding 40 mg/day (rounding 39 mg/day). The additional RDA was calculated as the EAR × 1.2, yielding 50 mg/day (rounding 46.8 mg/day).

2—3. Method Used to Set AI

2—3—1. Infants (AI)

The mean concentration of vitamin C in breast milk is 50 mg/L. The average milk intake is 0.78 L/day\(^{(8,9)}\), representing a daily vitamin C intake of about 40 mg/day (rounding 39 mg/day). This value was set as the AI.

The AI for infants aged 6 to 11 months was calculated using the average of the values from the following 2 expressions:
II Energy and Nutrients
Vitamins (2) Water-soluble Vitamins
Vitamin C

Expression 1: the AI for infants aged 0 to 5 months × (reference BW for infants aged 6 to 11 months/reference BW for infants aged 0 to 5 months) 0.75
Expression 2: the EAR for adults aged 18 to 29 years × (reference BW for infants aged 6 to 11 months/reference BW for adults aged 18 to 29 years) 0.75 × (1 + growth factor)

Thus, the AI was determined to be 40 mg/day for infants aged 6 to 11 months.

3. To Avoid Excessive Intake
3—1. Dietary Intake

Few regular foods contain more than 100 mg of vitamin C/100 g; however, no studies till date have reported unfavorable outcomes due to the excessive intake of regular food.

3—2. Method Used to Set the Tolerable Upper Intake level

Generally, the intake of vitamin C intake is regarded as safe for healthy individuals, as the excess intake merely results in a lower absorption rate from the intestine, and enhanced excretion in the urine following absorption\(^{(124,125,134)}\). Thus, no UL for vitamin C was set at present.

However, for patients with renal dysfunction, the intake of several grams of vitamin C may increase the risk of kidney stones\(^{(135,136)}\). Acute gastrointestinal intolerance was observed following excess intake; for example, an intake of 3 to 4 g/day induced diarrhea\(^{(137)}\). An intake higher than 1 g/day from supplements is not advised\(^{(124,125,138)}\).

4. For the Prevention of the Development and Progression of LRDs
4—1. The Association with LRDs
4—1—1. Prevention of Disease Development

Several reports have stated that there is no benefit in consuming more than 1 g/day of vitamin C\(^{(124–126,136)}\). The positive effects of vitamin C supplementation have not been clearly studied\(^{(132)}\).

4—1—2. Prevention of Disease Progression

No relevant data were available. The DG was not determined due to a lack of data.

5. Future Dietary Reference Intakes for Japanese

It is important to reconsider if the use of EAR and RDA, or DG is more appropriate for vitamin C in the DRIs. Additionally, the outcomes used in the setting of the DRIs should also be reviewed in the future.
